

Calculating Exponential Growth in Sweden and Mexico

Supplemental Handout for Lecture 2

January 20, 2023

In Lecture 2, we saw this question:

Demographic Transition in Sweden and Mexico (Crude Rates)

Sources: B.R. Mitchell, *European Historical Statistics 1750-1970* (1976): table B6; Council of Europe, *Recent Demographic Developments in Europe 2001* (2001): tables T3.1 and T4.1; CELADE, *Boletín demográfico* 69 (2002): tables 4 and 7; Francisco Alba-Hernandez, *La población de México* (1976): 14; and UN Population Division, *World Population Prospects: The 2002 Revision* (2003): 326.

Exercise: How much did Swedish pop grow from 1800 to 1900?
Mexico from 1920 to 2000? Answer can be approximate. We want a number, e.g 600%. Hint: approximate average growth rate and use exponential formula.

How do we approach it?

Answer: Remember our exponential growth rate formula

$$N(t) = N(0)e^{Rt}$$

We are interested in the increase, i.e. the ratio $\frac{N(t)}{N(0)}$. So we want to calculate e^{Rt} .

For Sweden, t is 100 and for Mexico, the same number is 80. However, R , the difference between crude birth rate b and crude death rate d , fluctuates during those time periods. There are thus two ways of calculating our desired ratio, either by using an average value of R over the period (this is what we did in class through a simple visual inspection of the graph).

The other way to do this is to realize that in e^{Rt} , Rt can be broken up into the sum of individual units of t (years) and the value of R associated with them. We could write $e^{R_{1800} + R_{1801} + \dots + R_{1900}}$. Or if we knew that R was unchanging in years 1800 and 1801, we could write $e^{R_{1800} \times 2 + \dots + R_{1900}}$.

It is difficult to precisely calculate the differences between b and d from this figure, but we can get a rough sense by visual inspection: from around 1810 to 1900, Sweden saw an R of around $10/1000 = .01$,

and from 1800 to 1810, it saw around $3/1000 = .003$ (there are some fluctuations between years, but this is not likely to make a big impact in this calculation). Using these numbers:

$$e^{.003*10+.01*90} = e^{0.93} \approx 2.5$$

This is of the same order of magnitude as the in-class number of a 2-fold increase.

Getting numbers from a visual inspection of the Mexico data is a bit harder, but we can get a rough idea: .016 from 1920-1935, .022 from 1935-1940, steadily increasing but with an average value of around .03 from 1940-1975, .034 from 1975-1980, and .015 from 1980-2000. This gives us:

$$e^{.016*15+.022*5+.03*35+.034*5+.015*20} = e^{1.87} \approx 6.5$$

This is of the same order of magnitude as the in-class number of a 7-fold increase

If interested, you can look at the graph more carefully and calculate a more precise estimate (or look for the source data online), but this is the general approach you would use.

A key point to note here is that this is an approximation—if we wanted a more exact number we would use integrals. But this approach can give us a relatively good estimate, and help us understand differences in the way in which demographic transition was experienced in these two countries, with Mexico growing faster in a shorter period of time as a result of a much higher R that outweighed any differences in t .
